3 **Abstract.** Over the last two decades, the Wang-Sheeley-Argé (WSA) Model
4 has evolved significantly. Beginning as a simple observed correlation between
5 the expansion factor of coronal magnetic field lines and the measured speed
6 of the solar wind at 1 AU (the WS model), the WSA model now drives NOAA's
7 first operational space weather model, providing real-time predictions of so-
8 lar wind parameters in the vicinity of Earth. Here, we demonstrate that the
9 WSA model has evolved so much that the role played by the expansion fac-
10 tor term is now largely minimal, being supplanted by the distance from the
11 coronal hole boundary (DCHB). We illustrate why, and to what extent the
12 three models (WS, DCHB, and WSA) differ. Under some conditions, all ap-
13 proaches are able to reproduce the grossest features of the observed quiet-
14 time solar wind. However, we show that, in general, the DCHB- and WSA-
15 driven models tend to produce better estimates of solar parameters at 1 AU
16 than the WS model, particularly when pseudo-streamers are present. Ad-
17 ditionally, we highlight that these empirical models are sensitive to the type
18 and implementation of the magnetic field model used: In particular, the WS
19 model can only reproduce in situ measurements when coupled with the PFSS
20 model. While this clarification is important both in its own right and from
21 an operational/predictive standpoint, because of the underlying physical ideas
22 upon which the WS and DCHB models rest, these results provide support,
23 albeit tentatively, for boundary-layer theories for the origin of the slow so-
24 lar wind.

1. Introduction

25 The prediction of interplanetary magnetic field (\mathbf{B}), velocity (\mathbf{v}), and to a lesser extent,
 26 number density (n), and plasma temperature (T) in the vicinity of Earth is a crucial
 27 component of any future reliable space weather capability [e.g. *Pizzo et al.*, 2011]. Yet,
 28 understanding and reproducing the structure of the inner heliosphere, even in the absence
 29 of obviously time-dependent phenomena such as coronal mass ejections (CMEs) is a chal-
 30 lenging task. Over the years, a variety of approaches to connect what is observed at the
 31 Sun with what is measured *in-situ* in the vicinity of Earth have been adopted, ranging
 32 from simple empirical relationships [e.g. *Wang and Sheeley*, 1990] to sophisticated global
 33 MHD models [e.g. *Riley et al.*, 2011]. Currently, the empirical models at least match, and
 34 arguably outperform the physics-based, first-principles models [*Owens et al.*, 2008b].

35 Global heliospheric models, such as WSA-Enlil [e.g. *Jian et al.*, 2011], and, more gen-
 36 erally, CORHEL [*Riley et al.*, 2012a], produce time series of \mathbf{B} , \mathbf{v} , n , and T at 1 AU
 37 in two key steps. First, a synoptic map of the photospheric magnetic field is used as
 38 the primary driver of the coronal model, which may be a Potential Field Source Surface
 39 (PFSS) or MHD model [*Riley et al.*, 2006]. This component of the model typically spans
 40 the range from $1R_S$ to $2.5R_S$ (PFSS) or $20 - 30R_S$ (MHD). Second, the heliospheric do-
 41 main ($20 - 30R_S$ to 1 AU, ~~say~~) is driven either directly using results from the coronal
 42 model or indirectly by constructing boundary conditions based on the topology of the
 43 coronal magnetic field [*Riley et al.*, 2001]. [Heliospheric boundary conditions derived from](#)
 44 [PFSS solutions at \$2.5R_S\$ are mapped outward without change to the inner boundary of](#)
 45 [the heliospheric model at \$30R_S\$.](#)

46 In this study, we focus on these indirect techniques used to derive the boundary con-
47 ditions, and particularly the solar wind speed, for the heliospheric model. Since the
48 structure of the solar wind is dominated by the dynamic pressure term in the momentum
49 equation ($\sim \rho v^2$), errors in determining the correct flow speed at the inner boundary of
50 the heliospheric model have the most significant impact on the heliospheric solutions.

51 Currently, there are three principal empirical techniques in use for computing [the](#)
52 [large-scale properties of](#) solar wind speed at some reference sphere (say, $30R_S$, beyond
53 which the flow is radial). First, the original Wang-Sheeley (WS) model (Wang and Shee-
54 ley, 1990) uses an observed negative correlation between solar wind speed (at 1 AU) and
55 the super-radial expansion factor of the solar magnetic field. Second, the “Distance from
56 the Coronal Hole Boundary” (DCHB) model [*Riley et al.*, 2001] specifies speed at the pho-
57 tosphere based on the perpendicular distance from the coronal hole boundary and maps
58 this speed out along field lines to $30R_S$. Third, the Wang-Sheeley-Arge (WSA) model
59 [*Arge et al.*, 2003], which, although considered to be a refinement to the WS model, in
60 fact, combines terms capturing both the WS and DCHB effects [*Arge et al.*, 2004]. Our
61 aim in this study is to identify the similarities and differences between these methods,
62 understand why they arise, and perform parametric studies of these techniques to assess
63 which model(s) produce(s) the best match with 1 AU measurements.

64 There remains confusion – or perhaps ambiguity – in the scientific community about
65 the precise definition of the WS, DCHB, and WSA approaches. *Shiota et al.* [2014], for
66 example modeled the global ambient structure of the inner heliosphere using what they
67 defined as the WSA model. They employed, however, an early version of the WSA model
68 that included only the expansion factor [*Arge and Pizzo*, 2000], and thus, should have

69 been defined as a variant of the WS model, or perhaps more specifically as WSA-2000.
70 In contrast, here we apply the most updated version of WSA, as defined by *Arge et al.*
71 [2003, 2004].

72 It is worth noting that the DCHB model is distinct from approaches relying on the
73 minimum angular distance from the heliospheric current sheet (HCS) [*Hakamada and*
74 *Akasofu*, 1981], in which the wind speed is assumed to slow in a band within some angular
75 minimum distance from the HCS, computed at some reference height (say $2.5R_S$ for PFSS
76 models or $20 - 30R_S$ for MHD models) and fast everywhere else. In particular, the DCHB
77 model specifies the slow wind along bands in the photosphere, adjacent to the open-closed
78 field line boundaries, and the resulting speed profile is then mapped along field lines to
79 some reference height. Only for highly idealized geometries, such as a tilted dipole field,
80 would these approaches be expected to produce similar results. Phrased another way,
81 the DCHB model describes the wind profile near its source, at the base of the corona,
82 whereas a technique based on distance from the HCS attempts to describe the profile at
83 some point of relative equilibrium. Comparisons of the WS model and a model based on
84 the the angular distance from the HCS with *in-situ* measurements, showed that the latter
85 resulted in substantially worse correlations with observations [*Wang and Sheeley*, 1997].

86 Previous studies that have assessed our ability to predict the bulk solar wind speed
87 have revealed that models are only modestly, if at all, better than “persistence” [e.g.
88 *Norquist and Meeks*, 2010], that is, that tomorrow’s speed, say, will be the same as the
89 current speed, “recurrence,” where the prediction is based on observed values 27 days
90 earlier [*Owens et al.*, 2013]. More recently, *Bussy-Virat and Ridley* [2014] developed a
91 probability distribution function (PDF) model for predicting solar wind speed by com-

92 binning a prediction based on the current value and gradient in solar wind speed as well
93 as its value one rotation earlier. They argued that the PDF model outperformed the
94 “persistence” model for predictions up to five days in the future (Pearson Correlation
95 Coefficient, $PCC \sim 0.52$), and the WSA model for predictions < 24 hours in advance.

96 While the specification of solar wind speed at $30R_S$, as outlined here, is empirical, the
97 prescriptions are linked to fundamentally different ideas on the origin of the slow solar
98 wind [Riley and Luhmann, 2012]. Thus, in principle, it may be possible to derive some
99 physical insight from comparisons of different empirical models. The WS model relies
100 on the expansion factor of the local flux tube to govern the resulting speed, density,
101 and temperature of the escaping solar wind. Detailed physics-based models have been
102 developed that suggest that the incorporation of waves and turbulence, in conjunction with
103 expansion factor may reproduce the basic properties of the slow and fast wind [Cranmer,
104 2010]. Other studies have argued that ~~the EF~~ expansion factor may even be able to account
105 for the unique compositional differences between slow and fast solar wind [Laming, 2004].
106 In contrast, the DCHB model prescribes slow solar wind adjacent to the boundary between
107 open and closed field lines, and fast wind everywhere else, and is more closely linked to
108 a “boundary layer” (BL) idea, such as “interchange reconnection,” for the origin of the
109 slow solar wind [Wang *et al.*, 1996; Fisk, 1996; Antiochos *et al.*, 2011], since it is at the
110 boundary between the open and closed field lines, i.e., the coronal hole boundaries, where
111 this reconnection is expected to take place. Thus, should either the WS or DCHB model
112 perform significantly better than the other, this would provide support for the underlying
113 physical mechanism.

114 In the sections that follow, we first describe these velocity map models, and then ap-
115 ply them to two specific Carrington rotations, 1913 and 2060. We perform a detailed
116 parametric study for these rotations, which were relatively quiescent and have been well
117 studied [e.g. *Riley et al.*, 1999; *Riley et al.*, 2012b]. Our goal here is not to firmly establish
118 what the best-fit parameters are in each model, but rather to understand what factors
119 drive the profiles that the models produce, and understand how the techniques are related
120 to one another. Following this, we compute solutions for all rotations from September
121 1995 through August 2010 (CRs: 1900 - 2100), i.e., spanning more than a solar cycle,
122 using a representative set of parameters for each model and compare the model results
123 with *in-situ* measurements. We conduct this exercise using both MHD and PFSS model
124 solutions. Finally, we draw some conclusions and suggest how future studies may build
125 upon this work.

2. The Velocity Map Models

126 In this section, we summarize the main properties of the WS, DCHB, and WSA models.
127 Since they rely on the concepts of ~~EF~~ expansion factor and the location of coronal hole
128 (CH) boundaries, we also discuss the relationship of these parameters to one another, as
129 well as to the location of the HCS. It is important to emphasize at the outset, that we are
130 exploring different implementations of these models that capture their salient features.
131 In particular, they cannot be referenced to specific versions of a particular model, since
132 the models themselves have undergone gradual and continuous changes over the years.
133 In fact, our parametric study aims at identifying an optimum set of parameters for each
134 model, at least within the confines of this study.

2.1. The Wang-Sheeley Model

135 The WS model is based on the observation that the speed of the solar wind measured
 136 at 1 AU negatively correlates with magnetic flux tube expansion factor (f_s) nearer the
 137 Sun [*Wang and Sheeley, 1990*]. Although the WS model was initially determined purely
 138 from comparisons of f_s with measured solar wind at 1 AU, a theoretical explanation for
 139 why such a relationship should hold was subsequently developed [e.g. *Wang et al., 2009*].
 140 An important aspect of this idea is that the production of the slow solar wind does not
 141 require any reconnection to open previously closed field lines.

142 Following [*Wang and Sheeley, 1997*], we can write the areal expansion factor, f_s as:

$$f_s = \left(\frac{R_S}{R_1}\right)^2 \frac{B_r(R_S, \theta_o, \phi_o)}{B_r(R_1, \theta_1, \phi_1)} \quad (1)$$

143 This expression relates the amount by which a flux tube expands from one location
 144 (r_o, θ_o, ϕ_o) , say at the solar surface ($r_o = R_S$) to another, usually higher in the corona
 145 (r_1, θ_1, ϕ_1) , e.g., $2.5R_S$ for PFSS models and $20 - 30R_S$ for MHD models. We note that the
 146 expansion factor is above and beyond the field expansion that would occur for a monopole
 147 field ($f_s \sim 1/r^2$).

148 More generally, we can write the WS relationship as:

$$V_{WS}(f_s) = V_{slow} + \frac{(V_{fast} - V_{slow})}{(f_s)^\alpha} \quad (2)$$

149 where v_{slow} is the lowest solar wind speed expected as $f_s \rightarrow \infty$, v_{fast} is the fastest solar
 150 wind speed expected as $f_s \rightarrow 1$, and α is, in principle, some coefficient also to be deter-
 151 mined *Arge and Pizzo [2000]*. Wang (Personal Communication, 2014) has advocated that

152 a value of $\alpha = 1$ is appropriate. In this limit, equation 2 reduces to the original rela-
 153 tionship proposed by *Wang and Sheeley* [1990]. Additionally, we also impose minimum
 154 and maximum speed limits of, say, 360, and 750 km/s (which could be free parameters)
 155 to account for the fact that this expression could potentially lead to speeds in excess of
 156 those observed by Ulysses for quiet solar wind conditions.

2.2. The “Distance from the Coronal Hole Boundary” Model

157 The DCHB model depends on the angular, minimum (perpendicular) distance from
 158 the coronal hole boundary to specify the solar wind speed [*Riley et al.*, 2001]. This is
 159 computed at the photosphere and the speeds are mapped along field lines to the reference
 160 sphere, $30R_S$, in this case. The DCHB model can be expressed as:

$$V_{DCHB}(d) = V_{slow} + \frac{1}{2}(V_{fast} - V_{slow}) \left(1 + \tanh \left(\frac{d - \epsilon}{w} \right) \right) \quad (3)$$

161 where d is the minimum, or perpendicular distance from an open-closed boundary, that
 162 is from a CH boundary, at the photosphere, ϵ is a measure of how thick the slow flow
 163 band is, and w is the width over which the flow is raised to coronal hole values [*Riley*
 164 *et al.*, 2001]. The parameters V_{slow} and V_{fast} are analogues (but, given the difference in
 165 formulation, likely to be different) to the same-named parameters in the WS model. At
 166 the boundary between open-closed fields, this expression reduces to V_{slow} , whereas, far
 167 from such a boundary, that is, deep within a coronal hole, it reduces to V_{fast} . For the
 168 DCHB model, then, the specification of the velocity profile depends only on the minimum
 169 distance of the field line foot-point to a coronal hole boundary.

2.3. The Wang-Sheeley-Argé Model

170 The WSA model has been successively refined since its initial development in the late
 171 1990's at NOAA's Space Weather Prediction Center (SWPC) and was recently a key com-
 172 ponent in the first research model transitioned to space weather operations [Farrell, 2011].
 173 It began life as a set of minor adjustments to the WS model, tuning the free parameters
 174 using more thorough comparisons with *in-situ* measurements. Then, the relationship was
 175 generalized, and a term based on the DCHB model was appended [Arge *et al.*, 2004]. The
 176 WSA prescription for solar wind speed at $30R_S$ is as follows :

$$V_{WSA}(f_s, d) = V_{slow} + \frac{(V_{fast} - V_{slow})}{(1 + f_s)^\alpha} (\beta - \gamma e^{-(d/w)^\delta}) \quad (4)$$

177 The parameters v_{slow} , v_{fast} , d , w , and α are similar to those defined for the WS and
 178 DCHB models. In addition, the parameters β , γ , and δ have been introduced. Moreover,
 179 the entire right-most bracketed term is sometimes raised to a power, e.g., $7/2$. According
 180 to Arge (Personal Communication, 2010), setting $v_{slow} = 240\text{km/s}$, $v_{fast} = 675\text{km/s}$,
 181 $\alpha = 1/4.5$, $\beta = 1$, $\gamma = 0.8$, $w = 2.8$, and $\delta = 3$ produce the best matches with GONG and
 182 SOLIS measurements. It should be noted, however, that some of these parameters are
 183 adjusted for different observatories. For Mount Wilson and Wilcox solar observatories, for
 184 example, they found a better match using: $v_{slow} = 250\text{km/s}$, $v_{fast} = 680\text{km/s}$, $\alpha = 1/3$,
 185 $w = 4$, and $\delta = 4$, with β and γ remaining the same. In the interests of tractability,
 186 in this study, we will assume $\beta = 1$ and $\gamma = 0.8$, varying the remaining 5 parameters.
 187 In summary, we note that, for the WSA model, the specification of the velocity profile
 188 depends both on the minimum distance of the field line foot-point to a coronal hole
 189 boundary (d) as well as the expansion factor (f_s). In the limit that $\gamma \rightarrow 0$, the WSA model

190 approaches the WS model, and in the limit that $\alpha \rightarrow 0$, the WSA model approaches the
191 DCHB model.

192 We should emphasize that we are exploring different empirical techniques and our pre-
193 scription of the WSA model is not necessarily the same as that currently implemented
194 at NOAA and/or NASA’s CCMC. For example, the “official” WSA model incorporates a
195 Schatten current sheet model [*Schatten, 1971*], [which is omitted in our analysis](#). However,
196 we have attempted to distill the most salient features of each method.

2.4. Relationship between Expansion Factor, Coronal Hole Boundaries, and the HCS

197 Although they are distinct constructs, the expansion factors of coronal magnetic field
198 lines, the locations of coronal hole boundaries, and the position of the HCS are all comple-
199 mentary, but incomplete descriptions of the coronal magnetic field. In some sense, they
200 are the more traditional structures that define the “magnetic skeleton” of the Sun’s mag-
201 netic field. And, while newer concepts, such as quasi-separatrix layers, squashing factors,
202 and spines [*Longcope, 2005*] would probably provide a more rigorous description of the
203 underlying structure, since our focus here is on comparing techniques that rely on these
204 more established quantities, we will limit our discussion to them.

205 Consider first the expansion factor of open magnetic field lines. This is estimated by
206 the amount that the radial field has decreased from the photosphere to some reference
207 height in the corona, beyond the $1/r^2$ divergence one would expect for a monopole field.
208 Visually, it can be interpreted as the amount that a local bundle of open field lines expand
209 as you follow them up through the corona. Deep within large polar coronal holes, this is
210 a relatively low number, but closer to the boundary between open and closed field lines it

211 increases as field lines have to fan out more to fill the space left by the closed field lines.
212 Thus, at least intuitively, we would expect an inverse relationship between the distance
213 from the coronal hole boundary and expansion factor. However, other coronal structures
214 can modulate the value of the expansion factor, and these changes are not in any obvious
215 way related to the DCHB. Pseudo-streamers, for example, are white-light structures in
216 the corona built from double-loop systems [*Riley and Luhmann, 2012*]. While they are
217 associated with coronal hole boundaries, and so, within the DCHB idea produce slow wind,
218 they are also associated with anomalously small expansion factors, which, according to
219 the WS prescription, would imply very high speeds [*Riley and Luhmann, 2012; Wang*
220 *et al., 2007*].

221 The HCS is the heliospheric extension of the solar neutral line, that is, it separates
222 magnetic fields of one polarity from those of the opposite polarity. Coronal hole bound-
223 aries, which are defined at the solar surface, if traced up through the solar atmosphere,
224 merge together, and form the HCS. Therefore, one might anticipate at least a superfi-
225 cial association between the DCHB and the location of the HCS. However, going from
226 the photosphere to the origin of the HCS, one loses information about the structure of
227 coronal holes themselves. Thus, the HCS is a “filtered” proxy for the location of coronal
228 holes.

229 To illustrate the relationship between the location of coronal holes, the DCHB, ex-
230 pansion factor, and the location of the HCS, we have computed and displayed each
231 for CRs 1913 and 2060 in Figures 1 and 2, respectively. CR 1913 and 2060 are well-
232 studied intervals occurring at the cycle 22/23 minimum and just prior to the 23/24
233 minimum, respectively. These results were computed using solutions available online

234 at www.predsci.com/mhdweb. The top panel in each case shows that, during these peri-
235 ods, there were well established polar coronal holes poleward of 60° in both hemispheres.
236 The middle panel illustrates how the angular distance (in radians) from the boundary of
237 the nearest coronal hole appears, when mapped out along field lines from the base of the
238 corona to $30R_S$. The green line tracing through the minimum in the contours is the loca-
239 tion of the HCS, that is, where $B_r = 0$. Finally, the bottom panel summarizes the areal
240 expansion factor of magnetic field lines traced from $30R_S$ back to the surface of the Sun,
241 plotted with reference to their location at $30R_S$. The expansion factor is most sensitive to
242 the location of the HCS, with large expansion factors (i.e., low speeds) narrowly entrained
243 about it.

244 Focusing first on CR 1913 (Figure 1), we note several points. First, the only longitudinal
245 asymmetry in the coronal holes is due to an active region located near the equator at
246 $\sim 270^\circ$ longitude. This causes the two equatorial spurs in both polar coronal holes.
247 Second, the DCHB, which is a tracer for the band of slow wind, encompasses the HCS.
248 Thus, here, the two quantities are relatively well correlated with one another. It should
249 be noted, however, that there is considerably more structure in the DCHB. Clearly, the
250 DCHB produces a more complex velocity profile than could have been derived from a
251 technique based on angular distance from the HCS. Third, the expansion factor (bottom
252 panel) also traces the HCS closely, with largest values (corresponding to slow speed)
253 aligned with it. Fourth, the DCHB increases much more gradually than the expansion
254 factor decreases moving away from the HCS. Fifth, there are pockets of low [EF-expansion](#)
255 [factor](#) (deep purple) that branch off and return to the HCS (e.g., south of the equator,

256 centered at 240° longitude. This would correspond to wind speeds greater than over the
257 poles of the Sun.

258 Similar points can be made for CR 2060 (Figure 2). However, there are some important
259 distinctions. First, several lower-latitude coronal holes, as well as polar coronal hole
260 extensions were present. Consider the DCHB (and hence speed) profile at 240° longitude.
261 While there is a clear minima associated with the HCS in the southern hemisphere, at
262 $\sim -20^\circ$ latitude, a second minimum can be found in the northern hemisphere, at $+15^\circ$.
263 This structure, it turns out is associated with a pseudo-streamer [*Riley and Luhmann,*
264 2012]. Second, the DCHB profile is even more complex, with spurs of low values (and
265 hence low speeds) breaking away from the HCS and arcing back. Third, the apparent
266 presence of equatorial coronal holes has broken the relatively close association between
267 HCS, EF, and DCHB. As the bottom panel shows, EFs associated with the spurs in the
268 middle panel are regions of low [EF-expansion factor](#) and, hence, high speed. As noted
269 earlier, the presence of the pseudo-streamers provides an ideal way to differentiate between
270 the two models, with [EF-expansion factor](#) predicting fast speed [*Wang et al., 2007*] and
271 DCHB predicting slow speed [*Riley and Luhmann, 2012*]

272 To illustrate these concepts more concretely, in Figures 3 and 4 we summarize the
273 computed speeds at $30R_S$ for the WS, DCHB, and WSA models, together with the trace
274 that an equatorially-located spacecraft would measure. (Time runs from the right to the
275 left in this presentation). Considering the WS profile first (top panel): There is a band
276 of slow flow wind tracing the location of the HCS, but pockets of extremely fast (> 800
277 km/s) “hang” off it. In contrast, both the DCHB and WSA models show a much broader
278 band of slow flow also organized about the HCS. The residual effects of the WS model’s

279 $1/f_s^\alpha$ term can be seen in the WSA solution as very localized speed enhancements at
 280 $\sim 240^\circ$ and $\sim 300^\circ$ longitude.

2.5. Mapping Solar Wind Streams from $30R_S$ to 1 AU

281 Once \mathbf{B} and \mathbf{v} at $30R_S$ have been computed, they could be used as boundary conditions
 282 to drive a global heliospheric MHD model. However, for parametric sensitivity studies,
 283 such an approach is impractical: A single solution may take several hours to complete.
 284 Thus, even at modest resolutions, it would be infeasible to compute hundreds or thousands
 285 of solutions. As a pragmatic compromise, we developed a simple numerical algorithm for
 286 mapping solar wind streams from near the Sun to 1 AU or elsewhere in the solar system
 287 [Riley *et al.*, 2011]. It neglects magnetic and thermal pressure terms and is restricted
 288 to 1-D; however, it is robust and performs reasonably well. In particular, we found
 289 that this technique, when coupled with an acceleration model to account for the residual
 290 acceleration of the solar wind that occurs beyond $30R_S$, produced mappings at 1 AU
 291 that were substantially the same (CC = 0.98) as full three-dimensional heliospheric MHD
 292 solutions [Riley *et al.*, 2011].

3. Model Comparisons with *in-situ* Measurements

293 In this section, we describe comparisons for one specific interval in detail; CR 2060
 294 (August 2007). Next, we compute and interpret model predictions for a selection of 14
 295 Carrington rotations spanning from CR 1913 to 2083. Finally, we summarize a statistical
 296 study of model comparisons spanning the entire last solar cycle, from CR 1900 to 2080.

297 CR 2060 occurred toward the end of solar cycle 23 and was devoid of large-scale transient
 298 activity. Moreover, the ACE spacecraft was situated serendipitously at a location from

299 which it could sample both helmet and pseudo-streamer structure during the same rotation
 300 [*Riley and Luhmann, 2012*]. For each model solution for this interval, we used data from
 301 the MDI magnetograph onboard the SOHO spacecraft to compute either PFSS or MHD
 302 coronal solutions. Next, we: (1) computed velocity maps of the speed at $30R_S$; (2)
 303 mapped out the solution to 1 AU as described in Section 2.5; and (3) compared with
 304 *in-situ* measurements by ACE/Wind spacecraft.

305 For the case study, we defined hypercubes in the appropriate parameter space. For the
 306 WS model, the cube consisted of V_{slow} , V_{fast} , and $\Delta\phi$ ($10 \times 10 \times 10$); the last parameter be-
 307 ing included in the analysis to account primarily for any phase mismatch caused by the fact
 308 that the wind has an acceleration profile from the solar surface to $30R_S$, which is not ac-
 309 counted for in these simple models. For the DCHB model, we considered a 5-D hypercube
 310 (~~$6 \times 6 \times 6 \times 6 \times 6 \times 106$~~ $\times 6 \times 6 \times 6 \times 10$) consisting of the four intrinsic model parame-
 311 ters plus $\Delta\phi$ and a 6-D hypercube (~~$6 \times 6 \times 6 \times 6 \times 6 \times 6 \times 106$~~ $\times 6 \times 6 \times 6 \times 6 \times 10$) for
 312 the WSA model. Table 1 summarizes the hyper-volume of parameter space for each of
 313 the three models. These ranges were based on a series of preliminary calculations aimed
 314 at constraining the multi-dimensional parameter space.

315 Rather than using a technique such as steepest descent to trace our way to the min-
 316 imum (optimum solution) in this parameter space, because the algorithm was relatively
 317 quick, we constructed solutions for every point in the hypercube, retaining only those
 318 that optimized the PCC as well as the root mean square error (RMSE) with observations
 319 ~~at 1 AU.~~ The PCC is a measure of the linear correlation between two variables, where
 320 total positive/negative correlation is given by +1/-1 and no correlation is given by zero.
 321 The RMSE, on the other hand, is a measure of the standard deviation of the differences

322 between predicted and observed values. This allowed us to explore the global properties
323 of minima within the parameter space, while still providing approximate estimates for the
324 optimal parameters. For simplicity, we base our analysis exclusively on PCC-optimized so-
325 lutions. The distinctions between PCC, RMSE, and other viable metrics will be reported
326 elsewhere.

3.1. Case Study: CR 2060

327 In Figures 5, 6, and 7, we summarize examples of WS, DCHB, and WSA solutions
328 that produced the best correlations. We do not claim that, even for this rotation, these
329 are the optimum parameters; However, we do believe that they are representative of the
330 hypercube's global minimum.

331 Figure 5 presents a comparison of the WS model with observations for CR 2060. Panel
332 (a) shows the radial speed as a function of longitude and latitude. Several points are
333 worth noting. First, the speed at mid and high latitudes is only modestly above 400
334 km/s. This disagrees with Ulysses observations [*McComas et al.*, 2006], which suggest
335 that, at least during the declining phase and at solar minimum, the speed of the high-
336 latitude wind is ~ 760 km/s. Second, the highest speeds are located at, and around the
337 heliographic equator. Third, the slowest speeds undulate about the heliographic equator
338 (dark blue trace) following the location of the HCS. From Equation (1), we can understand
339 this distribution: Where the expansion factors are largest, around the HCS, the speeds
340 are slowest. More modest expansion factors produce the medium-speed wind populating
341 much of the map, and small pockets of low expansion factor produce the highest speed
342 winds (red bands).

343 To compare this trace with *in-situ* measurements we could: (1) map the model results
 344 out to 1 AU (as described in Section 2.5) and compare directly with observations; or (2)
 345 map the 1 AU observations back to $30R_S$ and compare directly with model results. Both
 346 approaches introduce errors; however, both offer complementary and distinct information.
 347 Focusing first on the comparison at $30R_S$, Figure 5(b) compares the velocity profiles at
 348 $30R_S$, a location sufficiently close to the Sun that dynamical effects, such as stream com-
 349 pression, should not have begun. Of course, the ballistically-mapped-back data cannot be
 350 purged of this evolution, which is the primary limitation of such a comparison. Neverthe-
 351 less, we infer that the WS model has captured perhaps two of the high-speed streams, but
 352 fails to predict slow solar wind at both the start and end of the rotation. Interestingly, it
 353 predicts localized “beams” of high-speed wind as the spacecraft intercepts regions of low
 354 expansion factor.

355 The comparison at 1 AU (Figure 5(c)) emphasizes the dynamic evolution of the streams.
 356 The localized high-speed streams have merged into generally fast solar wind. However, the
 357 main discrepancy is still present: The observations include slow wind during the second
 358 half of the rotation, whereas the WS model predicts fast wind. For this rotation, the best
 359 PCC that could be achieved was -0.061, with $V_{slow} = 500$ km/s and $V_{fast} = 1000$ km/s
 360 (Table 2).

361 Figure 6 makes a similar comparison using the DCHB model. The speed map in the
 362 top panel shows fast wind at high latitudes and a band of structured slow flow about the
 363 equator, matching the pattern in Figure 4(b). The overall speeds are somewhat lower
 364 than 1 AU measurements because there is an outward acceleration of wind beyond $30R_S$.
 365 Figure 6 (b) compares the ballistically-mapped back speed with the model results at $30R_S$.

366 From this, we infer an approximate agreement at the largest scales, with some notable
367 discrepancies, particularly between $85^\circ - 160^\circ$ longitude. At 1 AU (Figure 6 (c)), the
368 profile matches reasonably well. Of particular note is that the model predicts slow solar
369 wind from 210° through the remainder of the rotation, in agreement with observations.

370 Finally, in Figure 7, we show the same comparison using results from the WSA model.
371 Focusing on the distinguishing features between this and Figures 5 and 6, we note the small
372 “islands” of fast wind attached to the band of slow flow in the WSA solution. There is a
373 particularly long “wisp” of fast wind in the southern hemisphere between 110° and 190° .
374 However, since the spacecraft’s trajectory remained in the northern hemisphere, it would
375 not have intercepted this structure. In summary, the spacecraft profiles are substantially
376 similar to those of the DCHB model (Figure 6), and the degree of correlation ($PCC =$
377 0.672) is roughly the same for this rotation (Table 2).

3.2. Model Parameter Estimates for a Selection of Campaign Rotations

378 We extended our analysis to a selection of 14 Carrington rotations spanning from the
379 22/23 minimum to the 23/24 minimum, by computing hyper-matrices of solutions, varying
380 the input parameters for each of the three models. The parameter space explored for each
381 model is summarized in Table 1, which represent broad, but reasonable ranges for each
382 of these parameters. The solutions producing the highest PCC for each rotation and
383 model are summarized in Table 2. ~~As should be evident, these~~ These rotations were
384 not chosen because they resulted in high values of PCC, but were approximately equally
385 spaced between 1913 and 2083. In some cases, poor or even unavailable synoptic maps
386 necessitated a shift to an adjacent rotation. Considering first the value of PCC, we note:
387 (1) a strong variation from essentially no correlation ($PCC \sim 0$) to high correlation

388 ($PCC > 0.8$); and (2) the highest correlations occur at the beginning and end of the
389 interval, i.e., at near-solar minimum conditions. The values of the parameters are most
390 tightly clustered for the DCHB model, followed by the WSA, then WS model.

3.3. Parametric Study Spanning more than Three Solar Cycles

391 To estimate the robustness of the parameters we derived for the parametric studies in
392 Section 3.2, we conducted sensitivity studies for 200 rotations spanning Carrington rota-
393 tions 1900 through 2100 (September, 1995 through August, 2010). This corresponds to
394 more than one solar cycle and required data from both Kitt Peak's Vacuum Telescope
395 (KPVT) and SOLIS, the switch occurring at CR 2007. We chose representative parame-
396 ters based on the results in Table 2, combining the best repeated values for the rotations
397 with the highest PCC values. We repeated the exercise with other reasonable choices to
398 verify that, at least statistically, the results were not sensitive to which choice was made.
399 We reiterate, the model parameters chosen are not necessarily the optimum ones; it is
400 quite possible that they will depend on the magnetogram used to compute the solution,
401 the precise details of the model implemented, and may even have solar cycle dependencies.
402 We also confirmed that they were in reasonable agreement with the values in the original
403 papers outlining that particular method.

404 Historically, the WS, WSA, and DCHB models were developed and refined using differ-
405 ent global models. In particular, the WS and WSA models were validated against in-situ
406 measurements using PFSS models, while the DCHB model relied on MHD solutions. To
407 address this, we computed solutions using ~~both~~ results from both the PFSS and MHD
408 models.

409 In Figure 8 we present the computed PCCs for the WS, DCHB, and WSA models for
410 Carrington rotations 1900 through 2100 based on PFSS model solutions. If no magne-
411 togram data were available, that CR was omitted. Of the 200 possible solutions, 174 were
412 retained for analysis. Our PFSS model is virtually the same as that used by other re-
413 searchers [e.g. *Wang and Sheeley, 1990; Arge and Pizzo, 2000*], with the notable difference
414 that numerically, we rely on a finite difference scheme, rather than the spherical har-
415 monic approach [*Altschuler and Newkirk, 1969*], which, in principle, allows us to generate
416 solutions at much higher spatial resolution. The top panel summarizes the correlation
417 coefficient for each rotation while the middle panel shows an 11-rotation running average,
418 thus, emphasizing longer-term variability. The three histograms at the bottom show the
419 distribution of correlation coefficients.

420 Focusing first on panel (a), we note that the three techniques generally track one another
421 quite well, with the WS model systematically slightly lower, and particularly during the
422 interval from ~ 2007 through ~ 2009 (Figure 8, middle panel). This coincided with the
423 appearance of pseudo-streamers, which, as we have noted, represents conditions under
424 which the WS model is not likely to perform well [*Riley and Luhmann, 2012*]. We note
425 further that there is considerable variability from one rotation to the next.

426 The bottom panels of Figure 8 show how the PCCs are distributed: all three approaches
427 generally show positive correlations. The median (mean) value of the WS PCC is 0.27
428 (0.25), while the median (mean) values of the DCBH and WSA coefficients are 0.35 (0.34)
429 and 0.39 (0.35), respectively. Moreover, only 25% of the CRs produced PCCs exceeding
430 0.5 using the WS method, whereas 35% and 36% of the same CRs produced correlations
431 that exceeded 0.5 using the DCHB and WSA techniques.

432 In Figure 9 we show the equivalent plots based on the MHD solutions. Considering the
433 time series in the top panel, we note: (1) again, there is considerable variability from one
434 rotation to the next; (2) the PCC generally drops from 1996 through 2000-2002, then rises
435 and stays higher from 2004 through 2010; (3) the WS coefficient is systematically lower
436 than either the DCHB or the WSA coefficient; (4) the WS coefficient is notably lower
437 between CR 2060 through 2080; and (5) there are a few CRs where the WS coefficient is
438 significantly better than either the DCHB or WSA coefficients.

439 Panel (b) of Figure 9 shows that , on average, the WS model shows relatively poor
440 correlation throughout the entire interval, with a period around 2003-2004 that shows the
441 highest correlation. Both the DCHB and WSA models show larger average PCCs, with
442 the highest sustained correlations in the latter half of the period (2004-2010).

443 The most striking difference between the MHD results and those summarized in Figure 8
444 lies in how the distribution of WS model results has changed. Using the MHD solutions,
445 the average WS correlations were only slightly above zero. In contrast, when the PFSS
446 solutions are used to compute the WS model speeds, the resulting distribution (lower-
447 left, green histogram) is significantly more skewed to positive values, and is, at least
448 qualitatively, comparable to the DCHB and WSA results.

449 For the MHD solutions, the median (mean) value of the WS PCC is 0.06 (0.07), while
450 the median (mean) values of the DCBH and WSA coefficients are 0.40 (0.35) and 0.36
451 (0.33), respectively. Moreover, only 7% of the 174 CRs produced PCCs exceeding 0.5
452 using the WS method, whereas 40% and 34% of the same CRs produced correlations that
453 exceeded 0.5 using the DCHB and WSA techniques.

454 Unlike the WS model, the DCHB and WSA models do not seem to depend significantly
 455 on whether the input magnetic field is computed from an MHD or PFSS model. It
 456 could be argued that the MHD solutions provide slightly higher correlations on average;
 457 however, this could also be the result of parameters that were not optimally tuned for the
 458 PFSS field model.

4. Summary and Discussion

459 In this study, we have compared three different techniques for determining the profile
 460 of the bulk solar wind flow speed based on the structure of the coronal magnetic field.
 461 We found that the DCHB and WSA models performed substantially better than the WS
 462 model when an MHD solution was used as input. In contrast, when a PFSS solution was
 463 used, the WS technique improved significantly.

464 Our analysis showed that, regardless of whether an MHD or PFSS solution was em-
 465 ployed, the WS model was systematically worse than either the WSA or DCHB model
 466 from mid-2007 through mid-2009 (Figures 9 and 8). Although there may be other possi-
 467 ble explanations for this, we believe that the most compelling is that during this interval,
 468 pseudo-streamers were frequently present. As we have shown here and elsewhere [*Riley*
 469 *and Luhmann, 2012*], the WS model appears to fail in the vicinity of pseudo-streamers,
 470 where it predicts extremely fast wind, in contrast to the DCHB model, which, in agree-
 471 ment with observations, predicts slower wind.

472 This study demonstrates that the DCHB and WSA models produce results that are
 473 remarkably similar. It is worth understanding why this is so. From the expression for V_{wsa}
 474 (Equation (4)), we note that the WS contribution to the speed is of the form: $1/(1 + f_s)^\alpha$,
 475 where ~~$\alpha \sim 0.3$~~ ~~$\alpha \sim 0.4$~~ $\alpha \sim 0.3 - 0.4$ (Table 2). Assuming $\alpha = 0.3$, as suggested by Arge

476 (Personal Communication, 2014), with the expansion factor ranging from $6.5 \rightarrow 40$ for
 477 CR 2060, we estimate that this factor varies from 0.33 to 0.55 across the reference sphere.
 478 On the other hand, the DCHB-like term is of the form $(1 - 0.8e^{-(d/4)^4})$. Again, the MHD
 479 solution indicates that d varies from $0 \rightarrow 23^\circ$. Thus, the DCHB term varies from $0.2 \rightarrow 1$,
 480 and, therefore, modulates the speeds far more than the WS term in the WSA formula. To
 481 a large degree then, the WSA formula for computing solar wind speed is governed by the
 482 distance from the nearest coronal hole boundary, and not the flux tube expansion factor
 483 term. In fact, we suspect that the slightly lower PCC values from the WSA model, as
 484 compared with the DCHB model during the 2007-2009 interval (Figures 8 and 9) may be
 485 due to the presence of the WS-like term. Ironically, the presence of an expansion factor
 486 term in the prediction of the solar wind speed is lowering its predictive power.

487 There is a significant difference in the quality of the ~~SW~~-WS solutions computed using
 488 the MHD and PFSS magnetic fields. On the other hand, the DCHB and WSA model
 489 results are less sensitive to the input field configuration. We believe that the PFSS model,
 490 which requires that the field becomes radial at some specific height, say $2.5R_S$, is intro-
 491 ducing additionally variability into the expansion of the coronal fields lines, which is not
 492 present in the MHD solution, but which improves the accuracy of the WS approach.

493 Our study involved a number of assumptions and sources of errors that could potentially
 494 have affected our results and their interpretation. The photospheric magnetic fields used to
 495 drive the coronal solutions, for example, are not precisely known [e.g. *Riley et al.*, 2012a],
 496 which will impact a model's ability to predict solar wind speed at 1 AU. Moreover, the
 497 models are limited and contain assumptions that, in some cases, cannot be rigorously
 498 defended, such as quasi-stationarity (either on sub-rotation timescales or solar cycle), or

499 the lack of any turbulence or waves in the model solutions. However, it is precisely these
500 limitations that the study has attempted to estimate, and which are incorporated into
501 the computed PCCs.

502 Our incorporation of the parameter ϕ to account for shifts in longitude between the
503 model results and observations, while often improving the fit, suggests another source of
504 error that cannot be easily accounted for. As shown in Table 2, values between -14°
505 and $+14^\circ$ were often found. These represented the maximum allowable values for ϕ .
506 However, we could not justify using values larger than this based on any known physical
507 phenomena (e.g., acceleration of the solar wind from, say, $1R_S$ to $30R_S$). The values
508 computed for ϕ spanned this entire range, with no obvious systematic bias. In future
509 studies, we will attempt to understand the variability of ϕ and its relationship with other
510 model parameters, including input magnetograms, model type, and phase of the solar
511 cycle.

512 Here, we relied on estimates of the PCC to assess the quality of the model solutions. We
513 also computed RMSE, and while there were some discrepancies between which solution
514 was optimal, for the purposes of this study, they were not material. In addition to PCC
515 and RMSE, there are a number of other metrics that could be considered [e.g. *Owens*
516 *et al.*, 2008a]. In future studies, we plan to incorporate other types of skill scores, such as
517 the arrival time of sector boundary crossings into the analysis.

518 Ultimately, the ideal approach would be a systematic parametric study adjusting all
519 possible inputs, models, and parameters iteratively, using a multidimensional conjugate
520 gradient type technique, such as the steepest descent method. However, in practice, given
521 the time it takes to compute a single coronal solution, map speed profiles along field

522 lines, and compute heliospheric solutions, it would not be feasible to do this iteratively.
523 The analysis described here, of using a single set of synoptic maps, a limited set of semi-
524 empirical models, and a coarse hyper-grid of model parameters is a first-step toward this
525 goal. In future studies, we plan to investigate refinements to this analysis. For example,
526 are there systematic solar-cycle dependencies in the model parameters [e.g. *Lee et al.*,
527 2011]? Do some synoptic magnetograms (e.g., for a particular observatory or prepared in
528 a particular way) give consistently better matches? Are there any conditions under which
529 the WS model outperforms the DCHB or WSA models?

530 Should these results withstand further scrutiny, they suggest that the perpendicular
531 distance from the coronal hole boundary is the primary structural feature about which
532 the solar wind flow speed is organized. We may further theorize that such a result more
533 naturally favors a “boundary layer” explanation for the origin of the slow solar wind, such
534 as “interchange reconnection” or a Rayleigh-Taylor instability [*Suess et al.*, 2009], since
535 this component would naturally originate at the boundary between open and closed field
536 lines. On the other hand, the “expansion factor” theory, by definition, requires the slow
537 solar wind to be organized around variations in the flux tube expansion factor.

538 Our study, however, does not conclusively show that expansion factor plays no role.
539 Instead, we have suggested that its association with the boundary between open and
540 closed field lines is responsible for the observed correlation. On the other hand, it is
541 possible that expansion factor is playing a minor role in the modulation of solar wind
542 speed, perhaps in the fast solar wind and near coronal hole boundaries. Additionally,
543 we have computed expansion factor at a particular reference height ($2.5R_S$). It may be
544 that the detailed changes in expansion factor along a flux tube are also important, as has

545 been suggested by *Wang et al.* [2012] in relation to pseudo-streamers. Finally, it is worth
546 noting that there is tentative evidence that expansion factor may modulate the speed of
547 fast solar wind, relatively deep within coronal holes. For example, in a study by *McGregor*
548 *et al.* [2011], the WSA model produced small-scale modulations within large-scale polar
549 coronal holes, which appear to match Ulysses observations as it traversed the solar poles
550 in late 1994 through early 1995. Are these driven by the expansion factor term? Further
551 investigation of these open questions may form fruitful lines of research.

552 In closing, we reiterate the two main points of this study. First, the WSA model is driven
553 primarily (although not exclusively) by the distance from the coronal hole boundary. And
554 second, the DCHB and WSA models typically perform better than the original WS model,
555 which is based solely on the expansion factor of magnetic field lines, particularly when
556 pseudo-streamers are present.

Table 1. Size of hypercube used to identify optimum solutions

Model	V_{slow}	V_{fast}	α	ϵ	w	δ	ϕ
WS	200 \rightarrow 500	500 \rightarrow 1000	1.0 \rightarrow 1.0				$-14^\circ \rightarrow +14^\circ$
DCHB	200 \rightarrow 400	400 \rightarrow 600		0.02 \rightarrow 0.06	0.015 \rightarrow 0.035		$-14^\circ \rightarrow +14^\circ$
WSA	200 \rightarrow 400	550 \rightarrow 750	0.3 \rightarrow 0.5		0.1 \rightarrow 0.4	3 \rightarrow 5	$-14^\circ \rightarrow +14^\circ$

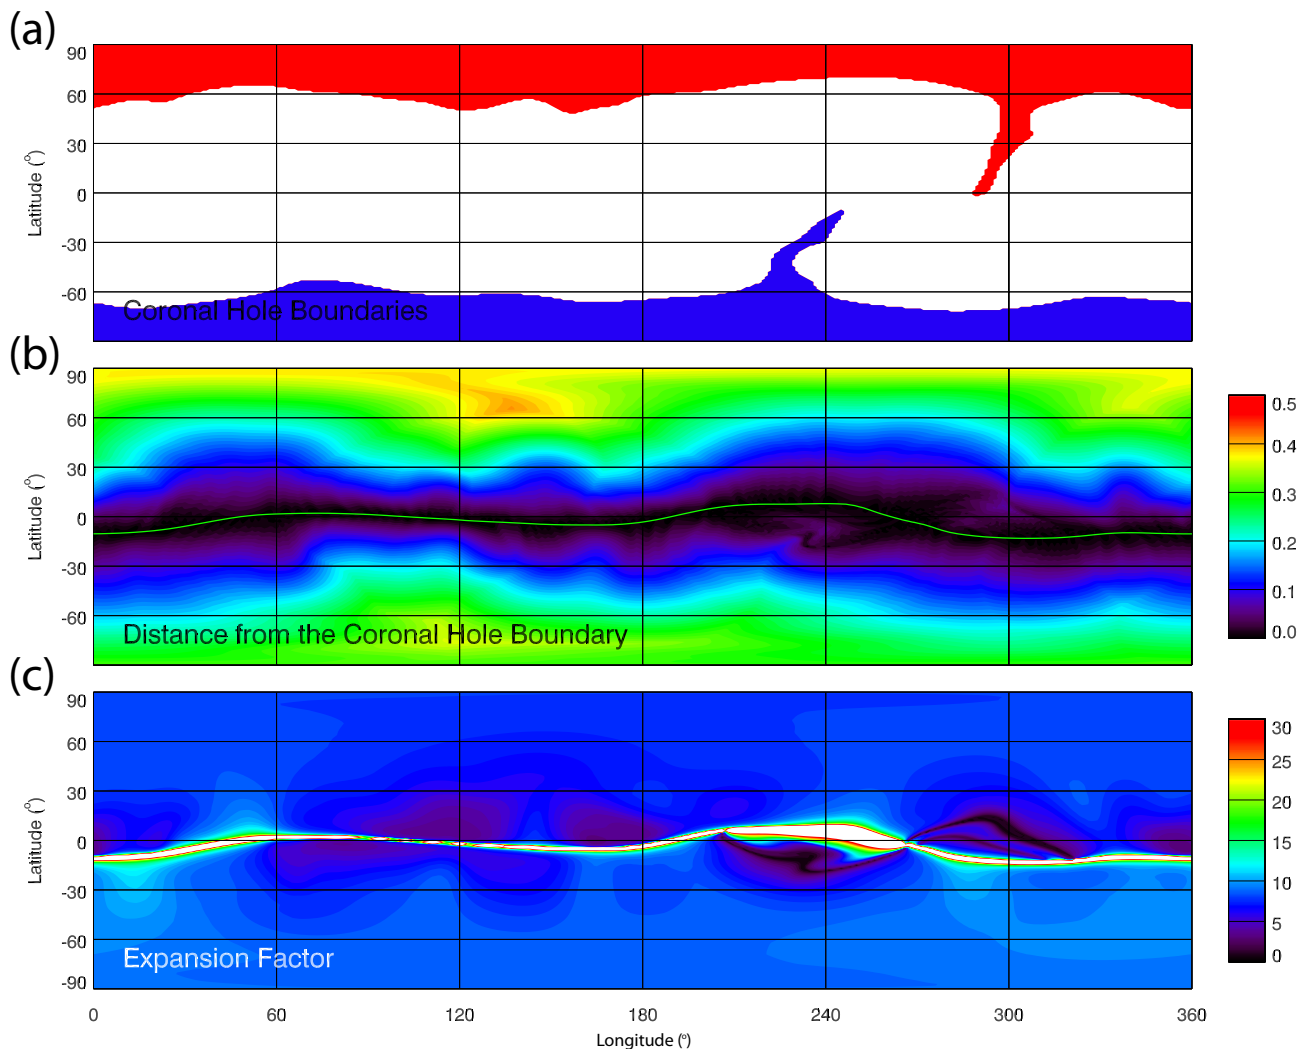

Figure 1. (Top) Coronal hole boundaries (at $1R_S$) as a function of heliographic longitude and latitude at the solar surface ($1R_S$) for Carrington rotation 1913. (Middle) Perpendicular distance from the nearest coronal hole boundary (in radians) at $30R_S$. The green line indicates the location of the HCS. (Bottom) the areal expansion factor of field lines, traced from $30R_S$ back to the solar surface but shown at $30R_S$. Values of $\text{EF-expansion factor} > 30$ are saturated and shown by the white band.

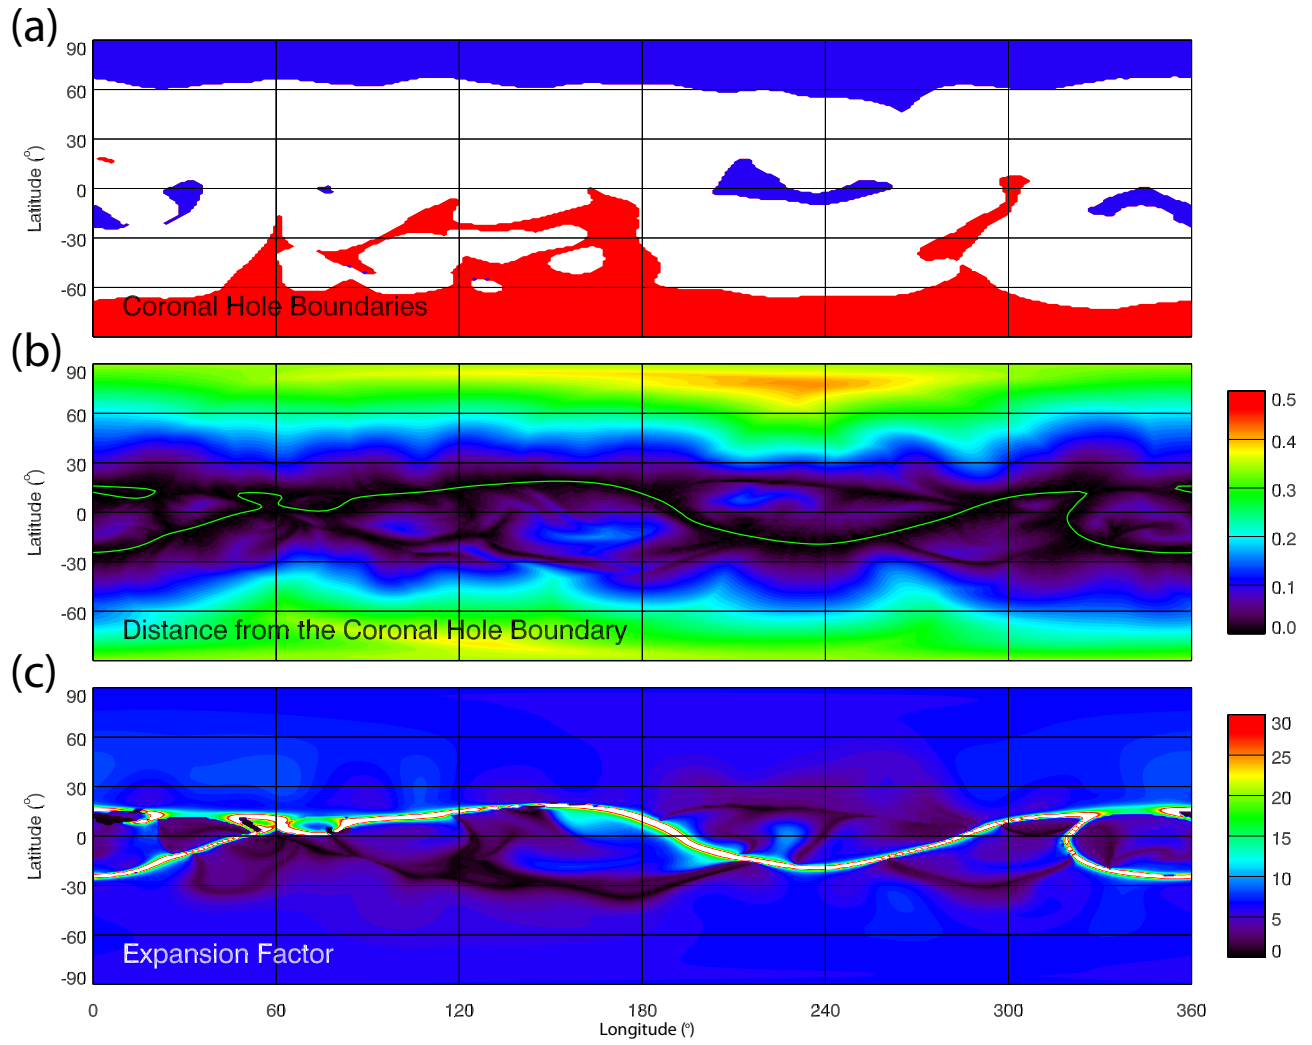

Figure 2. As Figure 1 but for CR 2060.

Figure 3. (a) Computed solar wind speed at $30R_S$ using the WS model as a function of longitude (x-axis) and latitude (y-axis) for CR 1913; (b) Computed solar wind speed at $30R_S$ using the DCHB model; (c) Computed solar wind speed at $30R_S$ using the WSA model; and (d) Comparison of the three model speeds at the equator as a function of Carrington longitude. The dashed curves give the computed solar wind speed $\sim \pm 1.25^\circ$ latitude above and below the spacecraft.

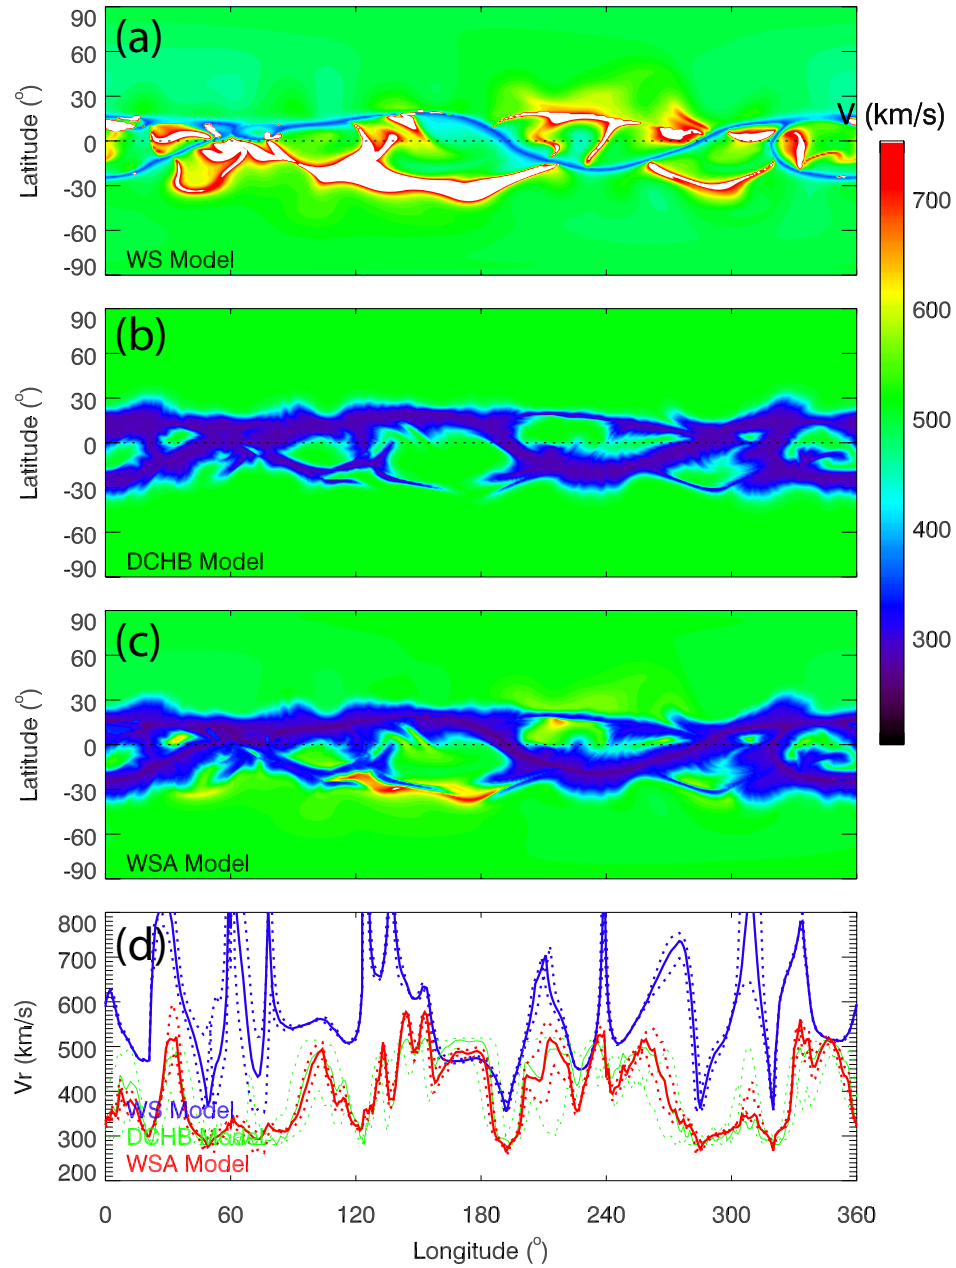

Figure 4. As Figure 3 but for Carrington rotation 2060.

Figure 5. (a) Speed map as a function of longitude (x) and latitude (y) at $30R_S$ for the Wang-Sheeley (WS) model for CR 2060. The solid straight line marks the trajectory of the spacecraft, with time increasing from right to left. (b) Comparison of computed speed (black) at $30R_S$ and ballistically-mapped *in-situ* measurements of speed (green) at Earth mapped to $30R_S$. (c) Comparison of computed (black) and observed (green) solar wind speed at Earth. The dotted red and blue lines show profiles at $\pm 2^\circ$ of the location of the spacecraft. The smooth green line is a 1-day running mean of the 1-hour *in-situ* measurements.

Figure 6. As Figure 5 but using the DCHB model.

Figure 7. As Figure 5 but using the WSA model.

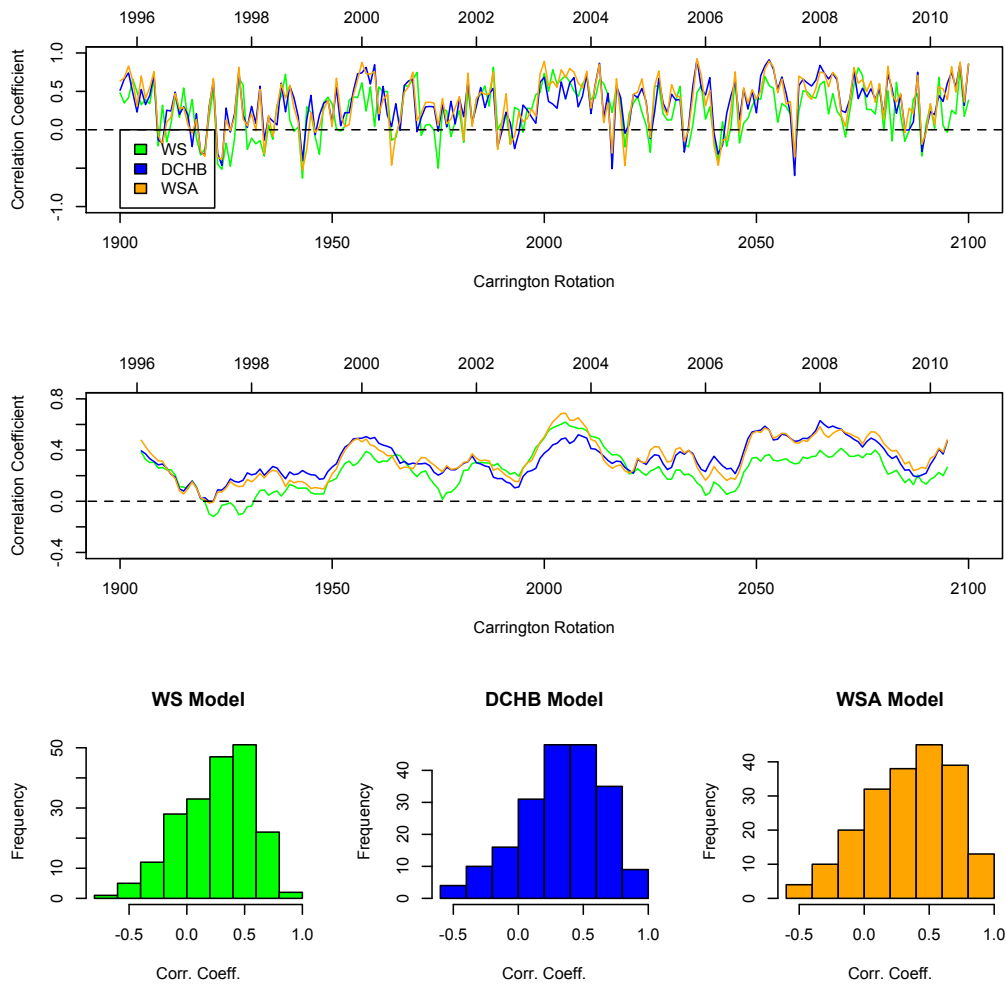

Figure 8. (a) Pearson correlation coefficients (PCCs) for the WS (green), DCHB (blue), and WSA (orange) as a function of Carrington rotation (or, equivalently, time) based on PFSS model solutions. (b) An 11-rotation running average of the PCCs. (c-e) Histograms of PCC for WS (c), DCHB (d), and WSA (e) models for the interval shown in (a) and (b).

Figure 9. As Figure 9 but the speed maps are generated using MHD solutions.

Table 2. ‘Optimum’ parameters for WS, DCHB, and WSA models for selection of Carrington rotations.

Model	CR	V_{slow}	V_{fast}	α	ϵ	w	δ	ϕ	PCC
